

## **Supplemental Information for**

### **"No link between population isolation and speciation rate in squamate reptiles"**

Sonal Singhal, Guarino R. Colli, Maggie R. Grundler, Gabriel C. Costa, Ivan Prates, Daniel L. Rabosky

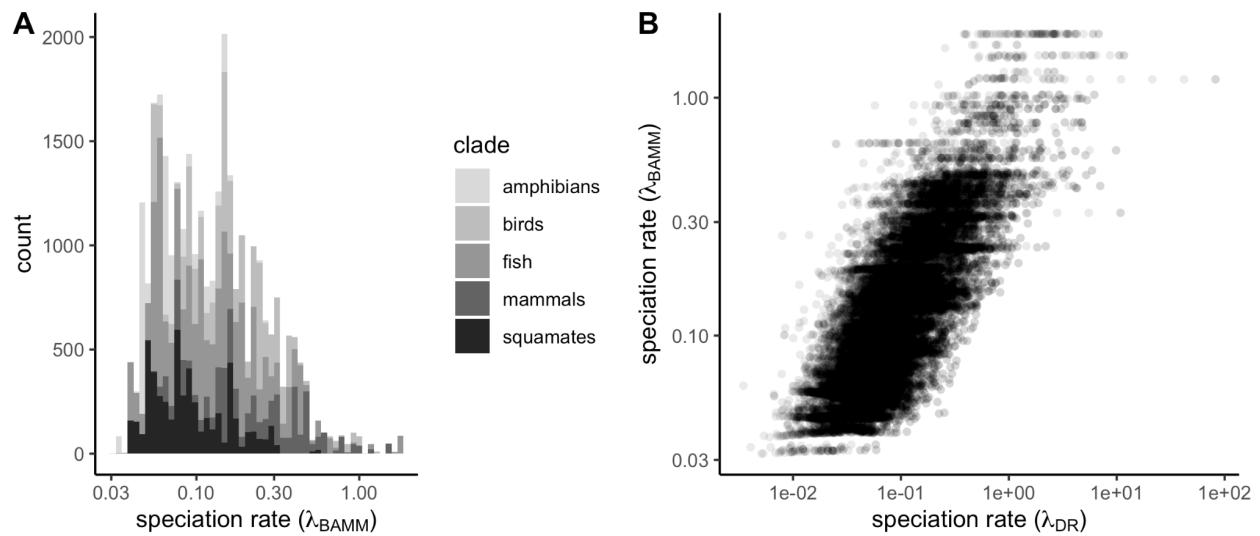

#### *Range map reconstruction*

To infer range maps for *Bothrops moojeni* and *Micrablepharus atticolus*, we used an approach based on cropping an alpha-hull model of all occurrence points by an ecological niche model (ENM) (1). Here, we used expert datasets on occurrence points of these two species (2, 3). We first constructed an alpha hull polygon around these points using the alphahull package in R (4). We then used MaxEnt (5) to construct ENMs for each of these species using the 18 BioClim variables at 2.5m resolution (6). We converted ENMs to ENM range maps with a threshold set at 3%. Finally, we clipped the alpha hull polygon to the extent of the ENM inferred range.

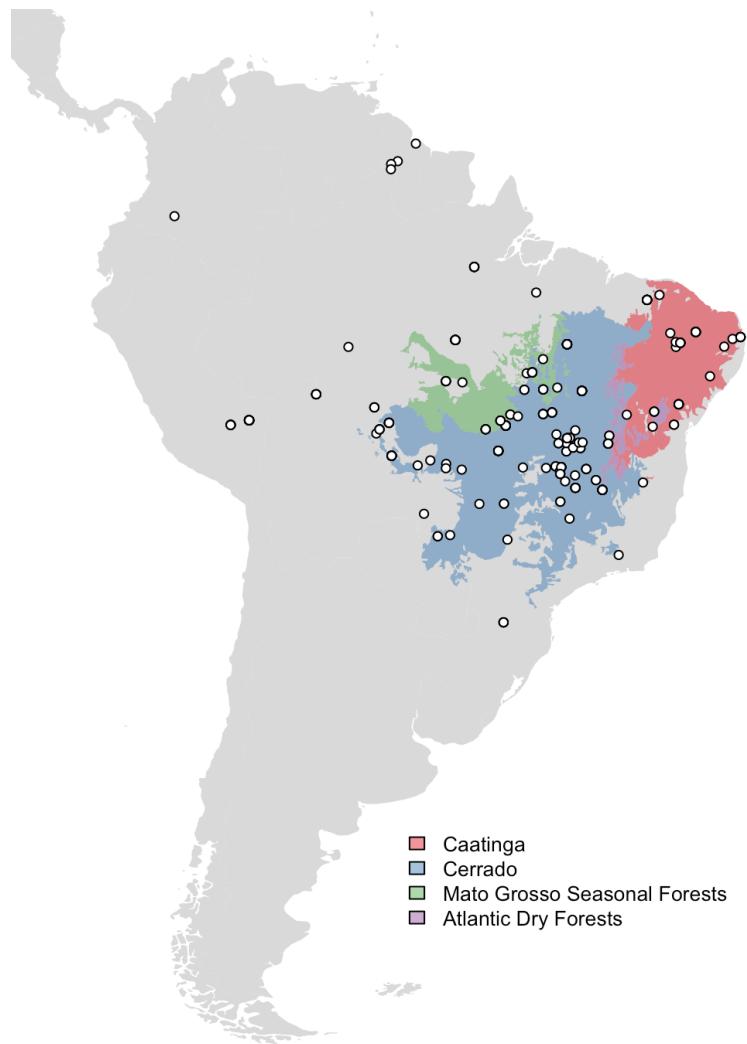

#### *Forward Genetic Simulations*

To test how sample size influences error in IBD estimates, we conducted a series of forward, individual-based simulations using the program SLiM v3.6 (7). These simulations are extensively borrowed from similar simulations of genetic differentiation across space (8, 9). At time 0, we initialized a population of hermaphroditic individuals across a square space that was 50 by 50 units. Each unit had a carrying capacity of 5 individuals for a total carrying capacity of 12,500 individuals. We simulated 5,000 loci of 3,000 base pairs each, with mutation rate of  $1 \times 10^{-8}$  and recombination rate of  $1 \times 10^{-8}$ . Three aspects of individual behavior are set by the parameter  $\sigma$ , which we treat here as the dispersal parameter: the distance individuals disperse from its parent and the distance that determines mate choice and competitive interactions among individuals. In each generation, individuals disperse, reproduce with individuals within  $3\sigma$  distance, and die as a function of local population density (local population size here is defined as  $3\sigma$ ). We ran five simulations across 4 values of sigma: 0.25, 0.5, 1.0, and 2.0. Simulations were run for 1e6 generations, at which point we recorded individual locations and output individual genotypes for segregating sites. We randomly sampled either 5, 10, 15 or 20 individuals to use for IBD estimation.

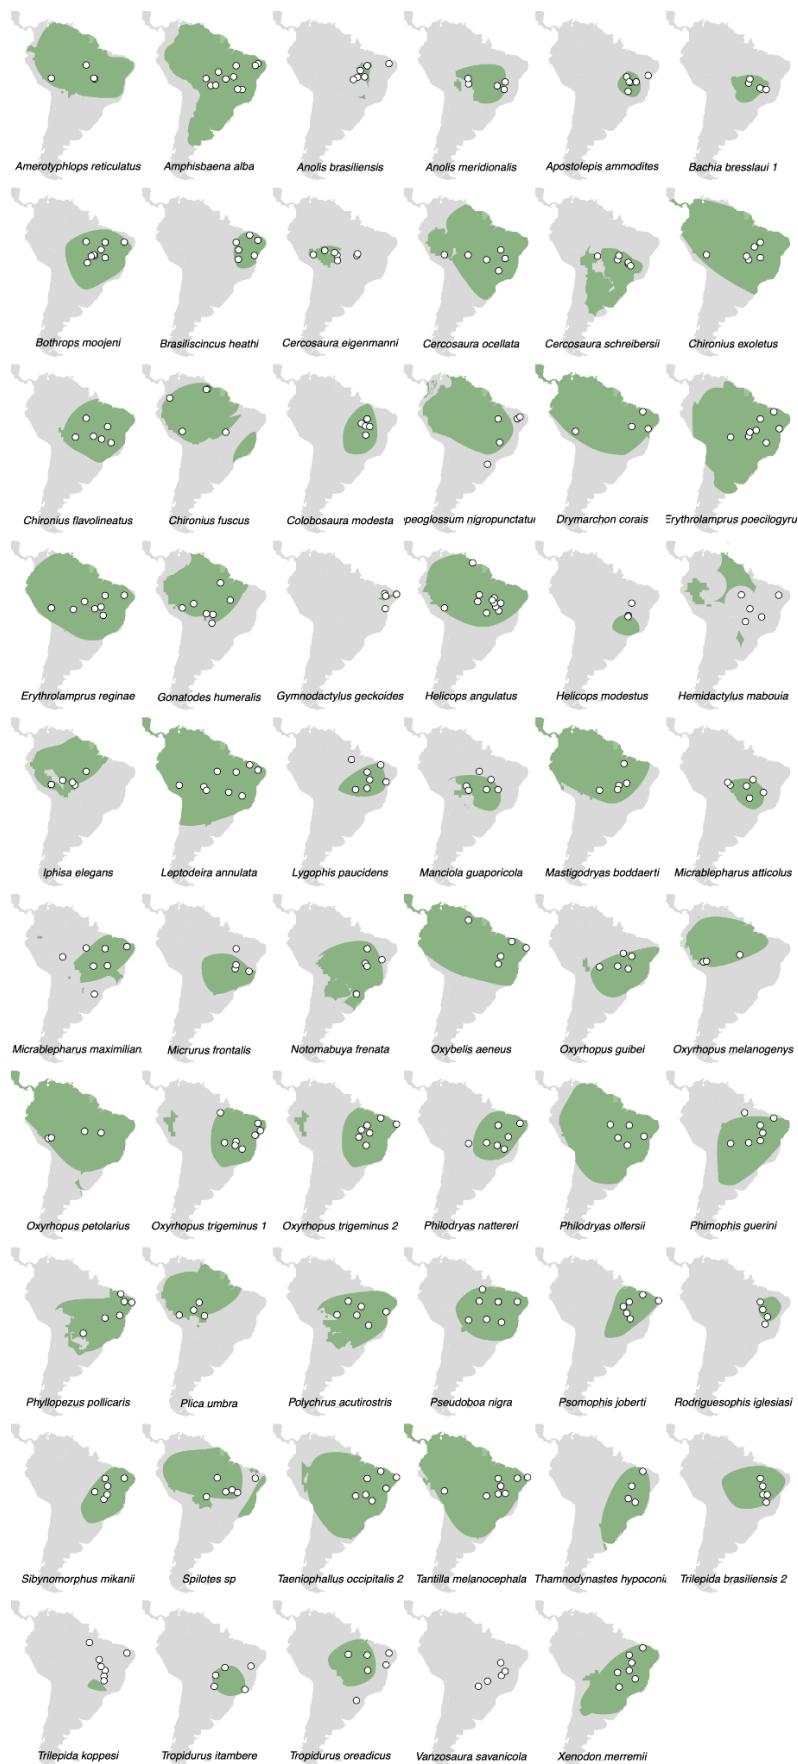

## Supplemental Figures

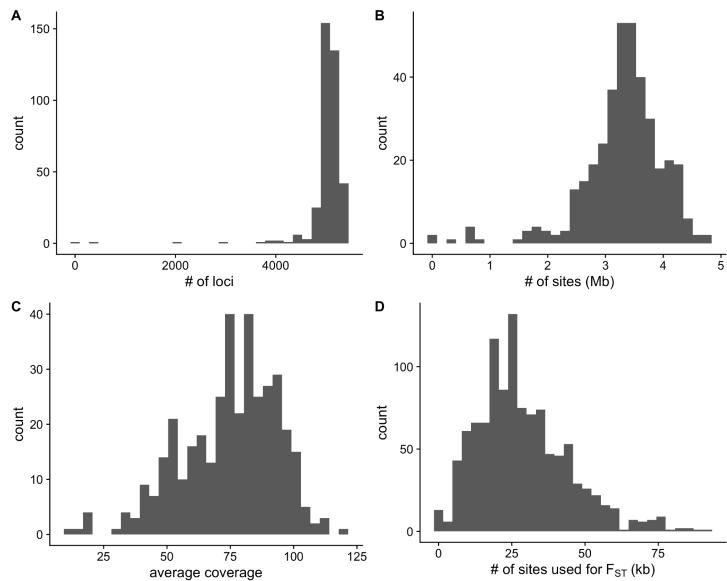

**Figure S1:** (A) Speciation rates across vertebrates; rates are estimated using the BAMM (10). The data are from Cooney & Thomas (2020; 11). Speciation rate distributions are highly skewed and are thus presented on a log10 scale. BAMM rates are known for being conservative (12); still, speciation rates across the fastest 1% and slowest 1% vary anywhere from 5-fold to 31-fold. Whether measured using the DR statistic (Fig. 1) or BAMM, speciation rates are highly variable across clades. (B) Speciation rates measured using the DR statistic and BAMM are highly correlated (non-phylogenetic  $r = 0.78$ ).

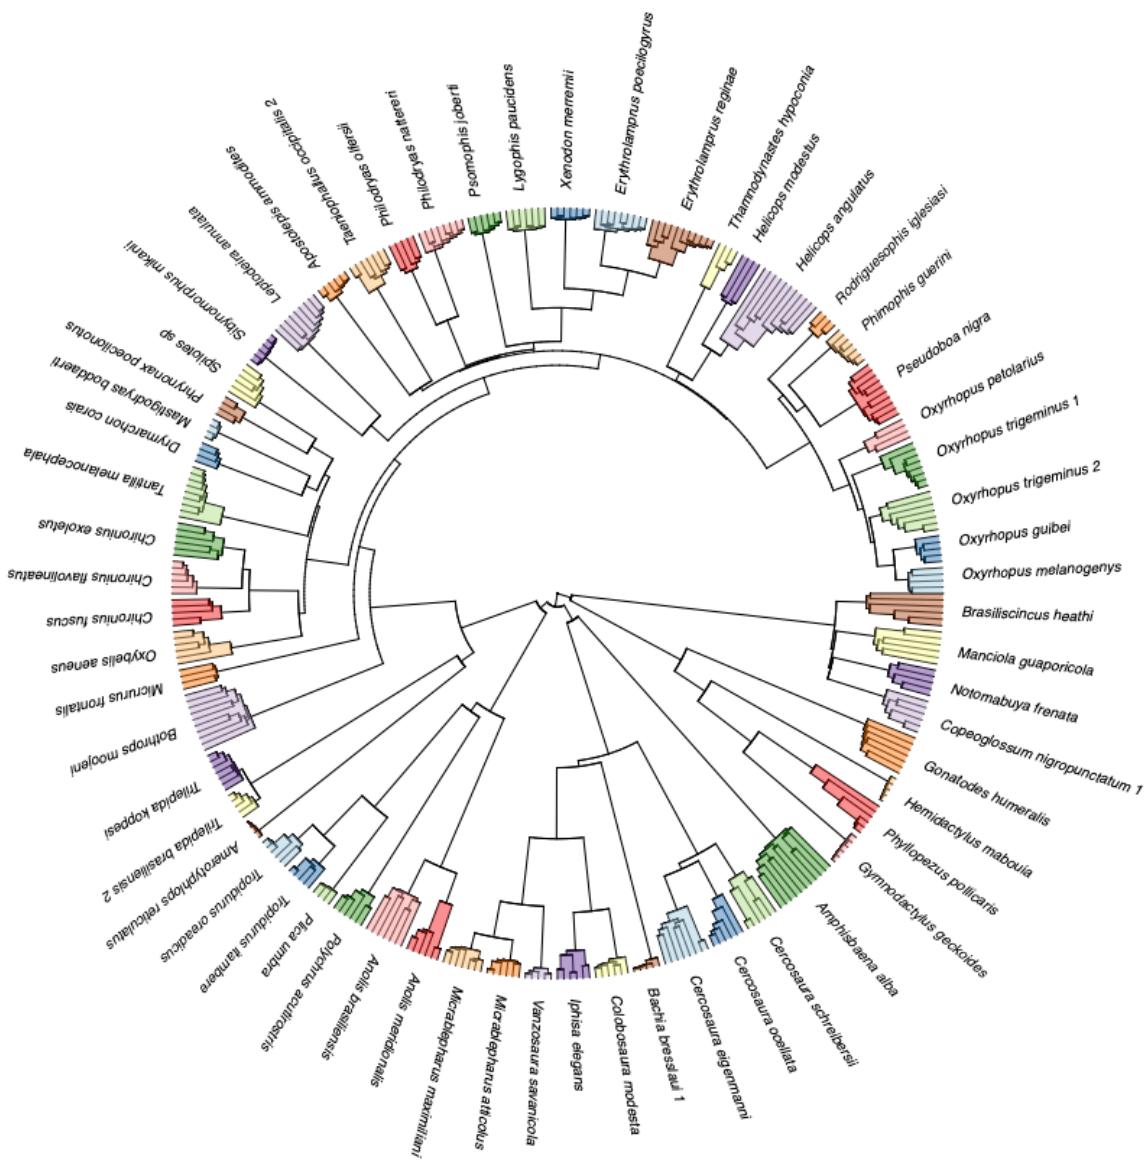

**Figure S2:** Map of the samples included in this study ( $n = 375$ ). Seventy percent of samples fall in one of four eco-regions that collectively make up South America's "Dry Diagonal" biogeographic region: the Caatinga, Cerrado, Mato Grosso Seasonal Forests, and Atlantic Dry Forests. This focused sampling helps control for some of the ecological and geographic factors that might also influence diversification rates.

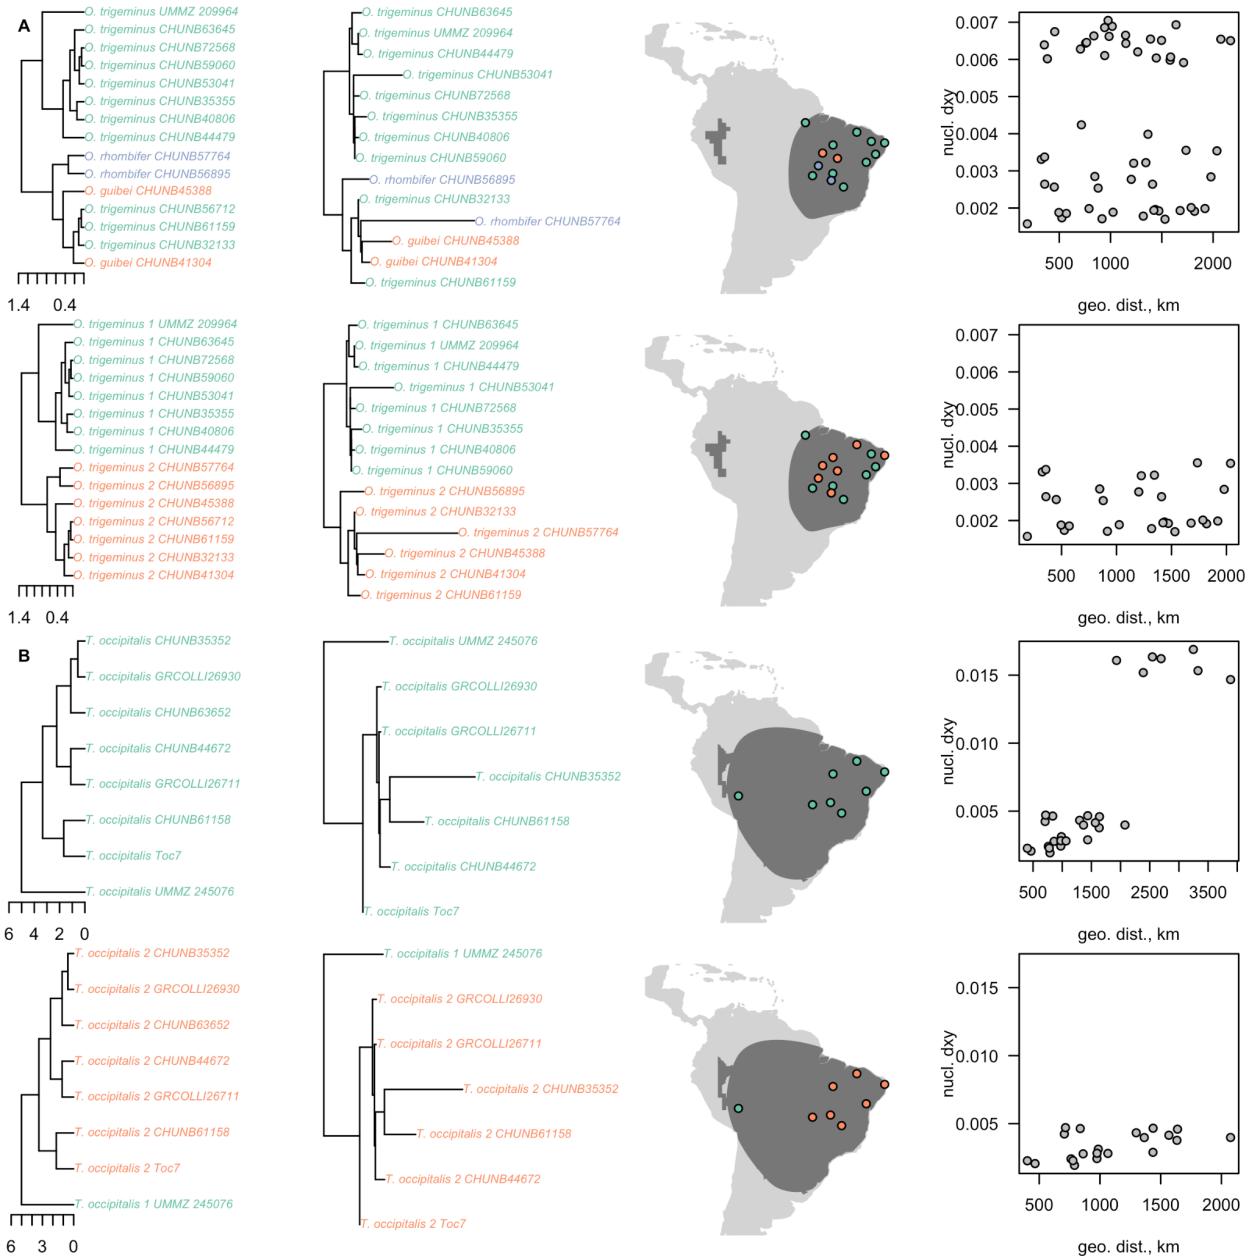

**Figure S3:** Geographic maps and sampling points shown for each operational taxonomic unit (OTU) included in this study. Geographic maps are from (13). Note that some geographic ranges do not encompass all points; geographic distributions are not well-circumscribed for many Neotropical species (2). Given uncertainty in geographic limits, our sampling (while relatively limited in number of individuals) spans most of the geographic range of most taxa.

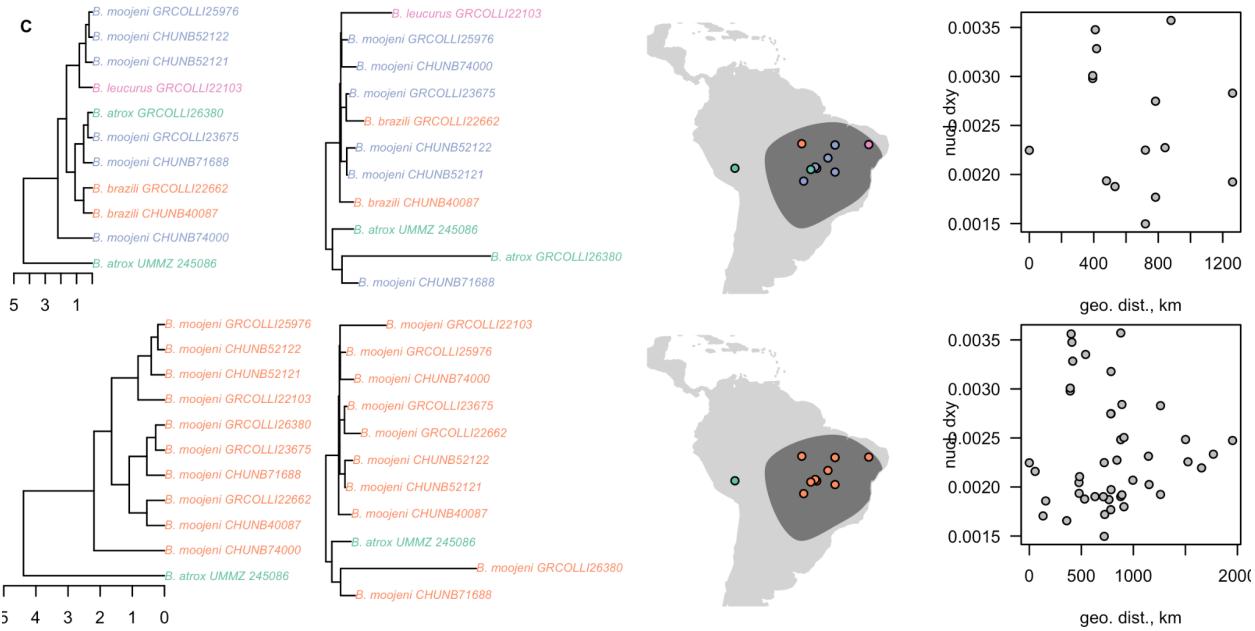

**Figure S4:** Data quality for the individuals ( $n = 375$ ) included in this study: (A) number of loci sampled (mean = 5019), (B) number of high-quality ( $\geq 20$ ) and high-coverage ( $\geq 10$ ) invariant and variant sites sampled (mean = 3.3 Megabases [Mb]), (C) average coverage across these sites (mean = 74.6), and (D) number of variable sites used for  $F_{ST}$  estimation (mean = 28.5 kilobases [kb]). Our genomic inferences were based on a high-quality, locus-rich dataset.

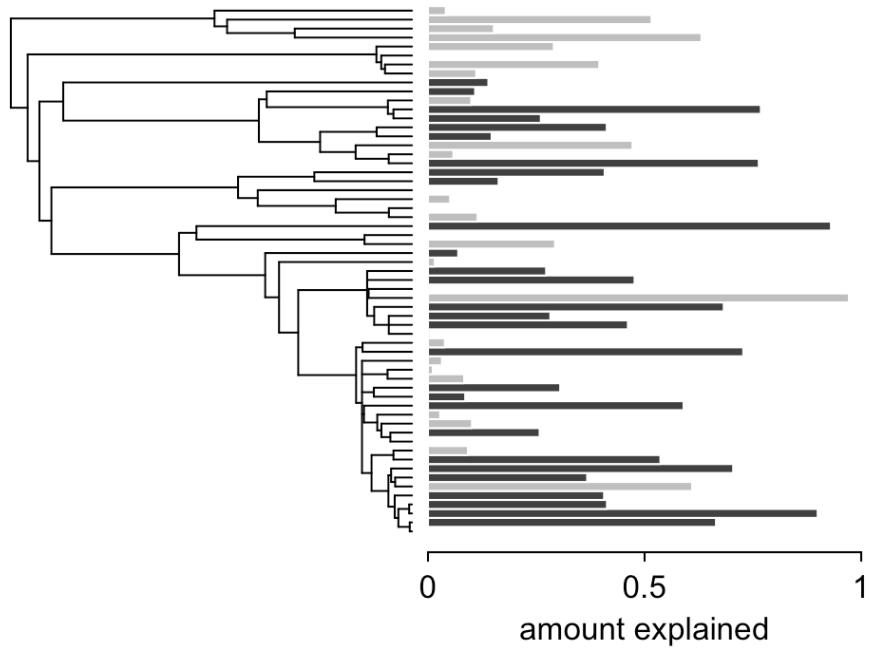

**Figure S5:** Concatenated phylogeny of 4796 loci across the 375 individuals included in this study. Phylogeny was dated using penalized likelihood (14) as implemented in the “chronos” function in the R package ape(15). The root age was set to 180 million years (16). Clades are colored by operational taxonomic unit (OTU) identity. While most taxa in our study correspond directly to accepted, nominal taxa, some taxa (23%) required taxonomic revision to reflect cryptic species or taxonomic uncertainties. This phylogeny was used solely to help guide OTU delimitation; inferences on speciation rate and other interspecific comparative analyses used the time-calibrated published phylogeny of Tonini et al. 2016.

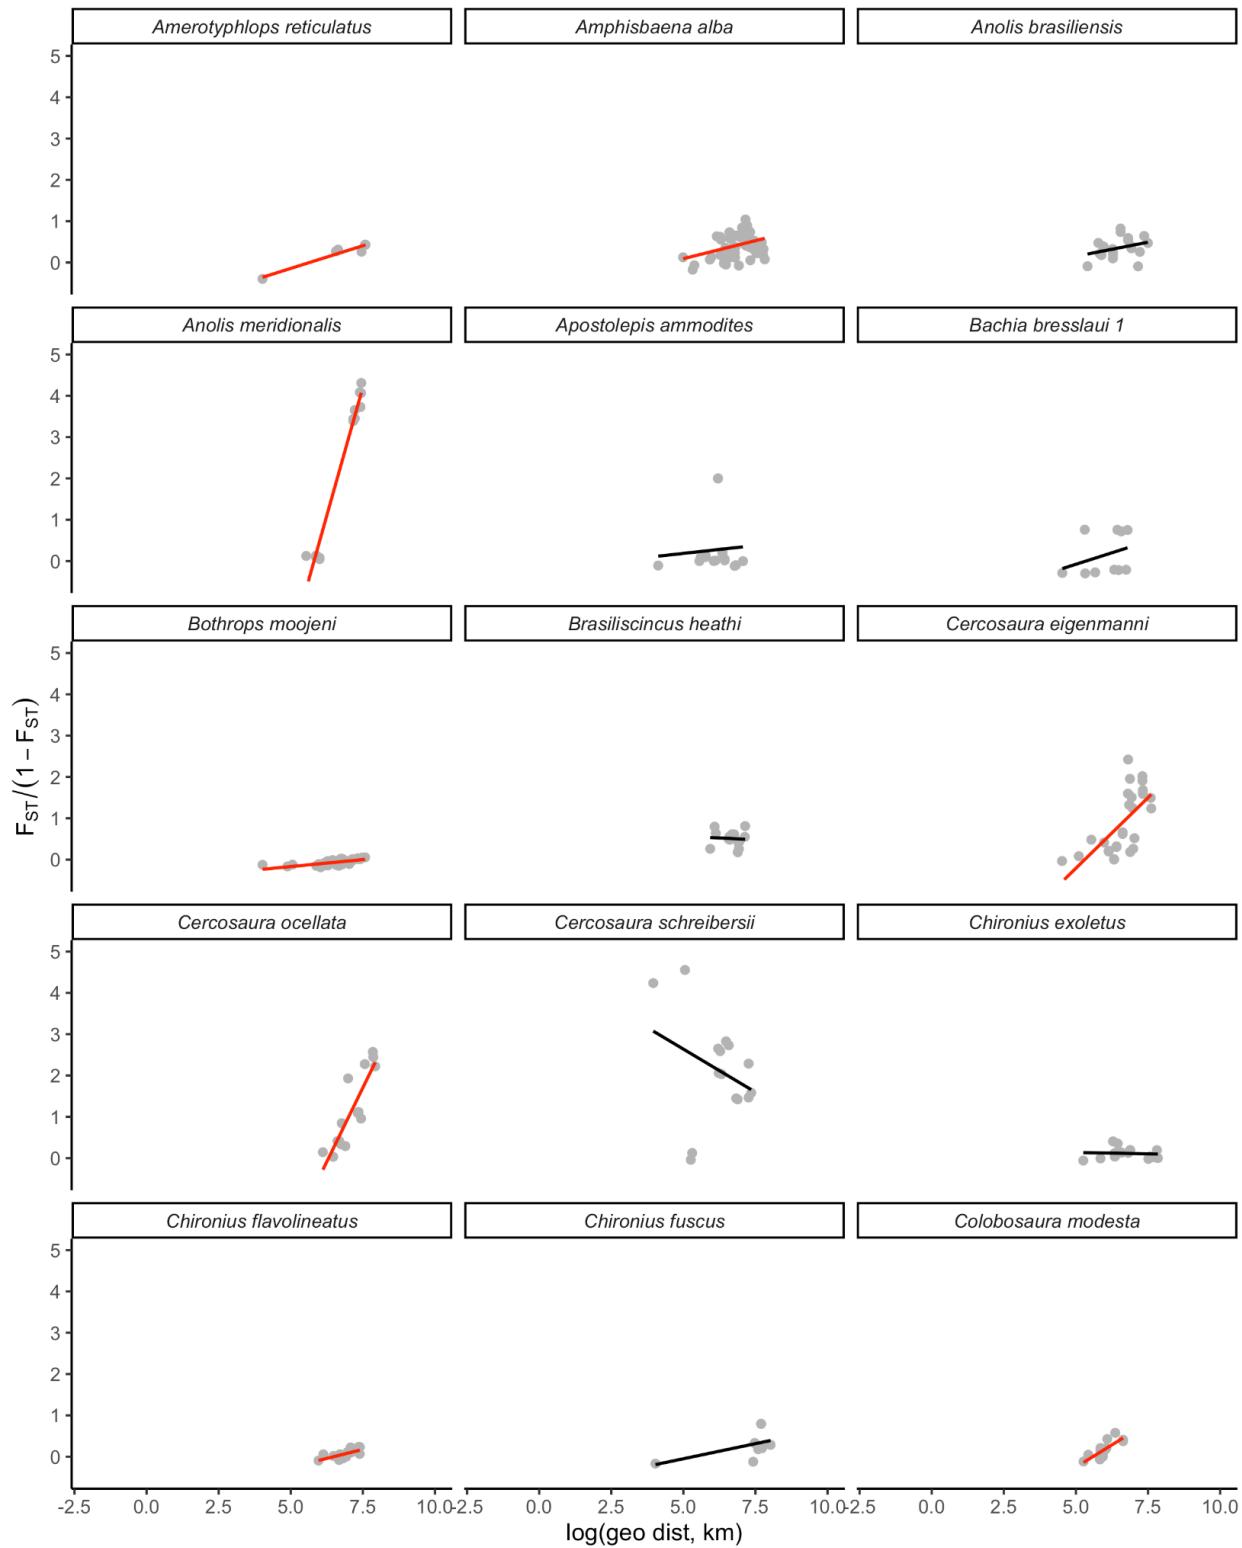

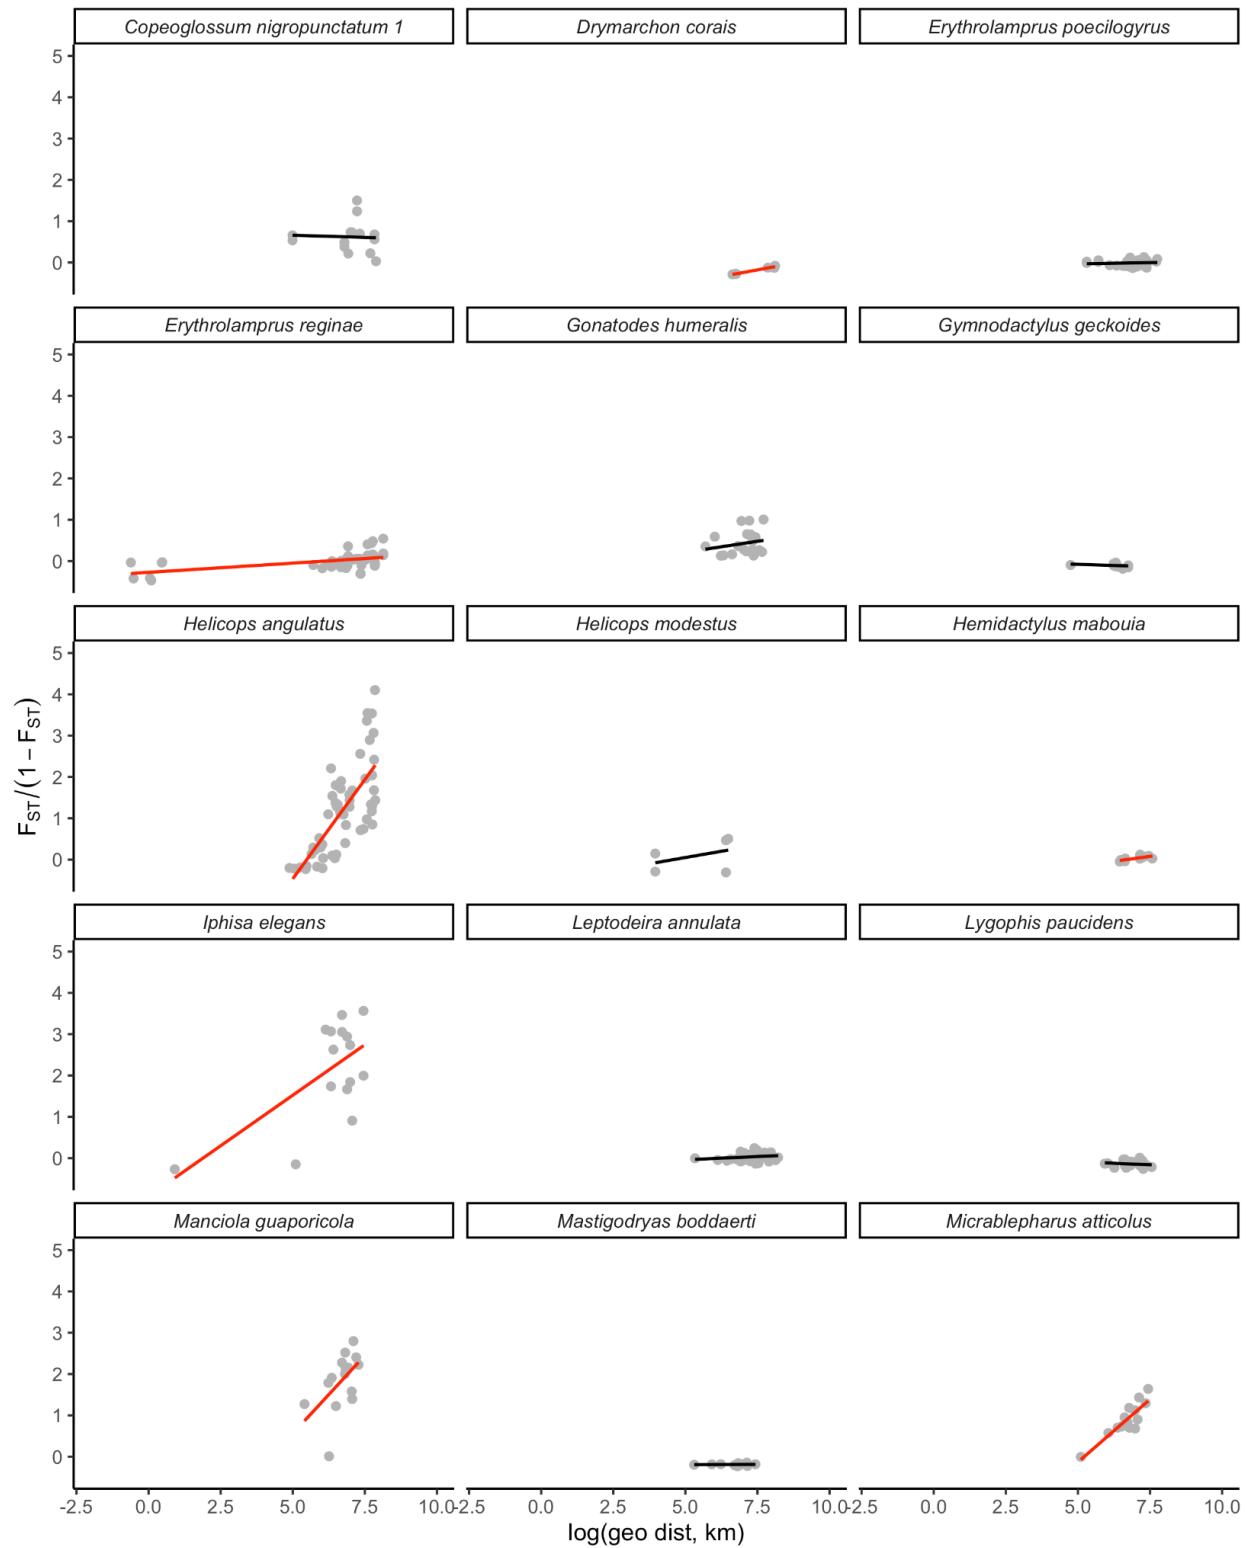

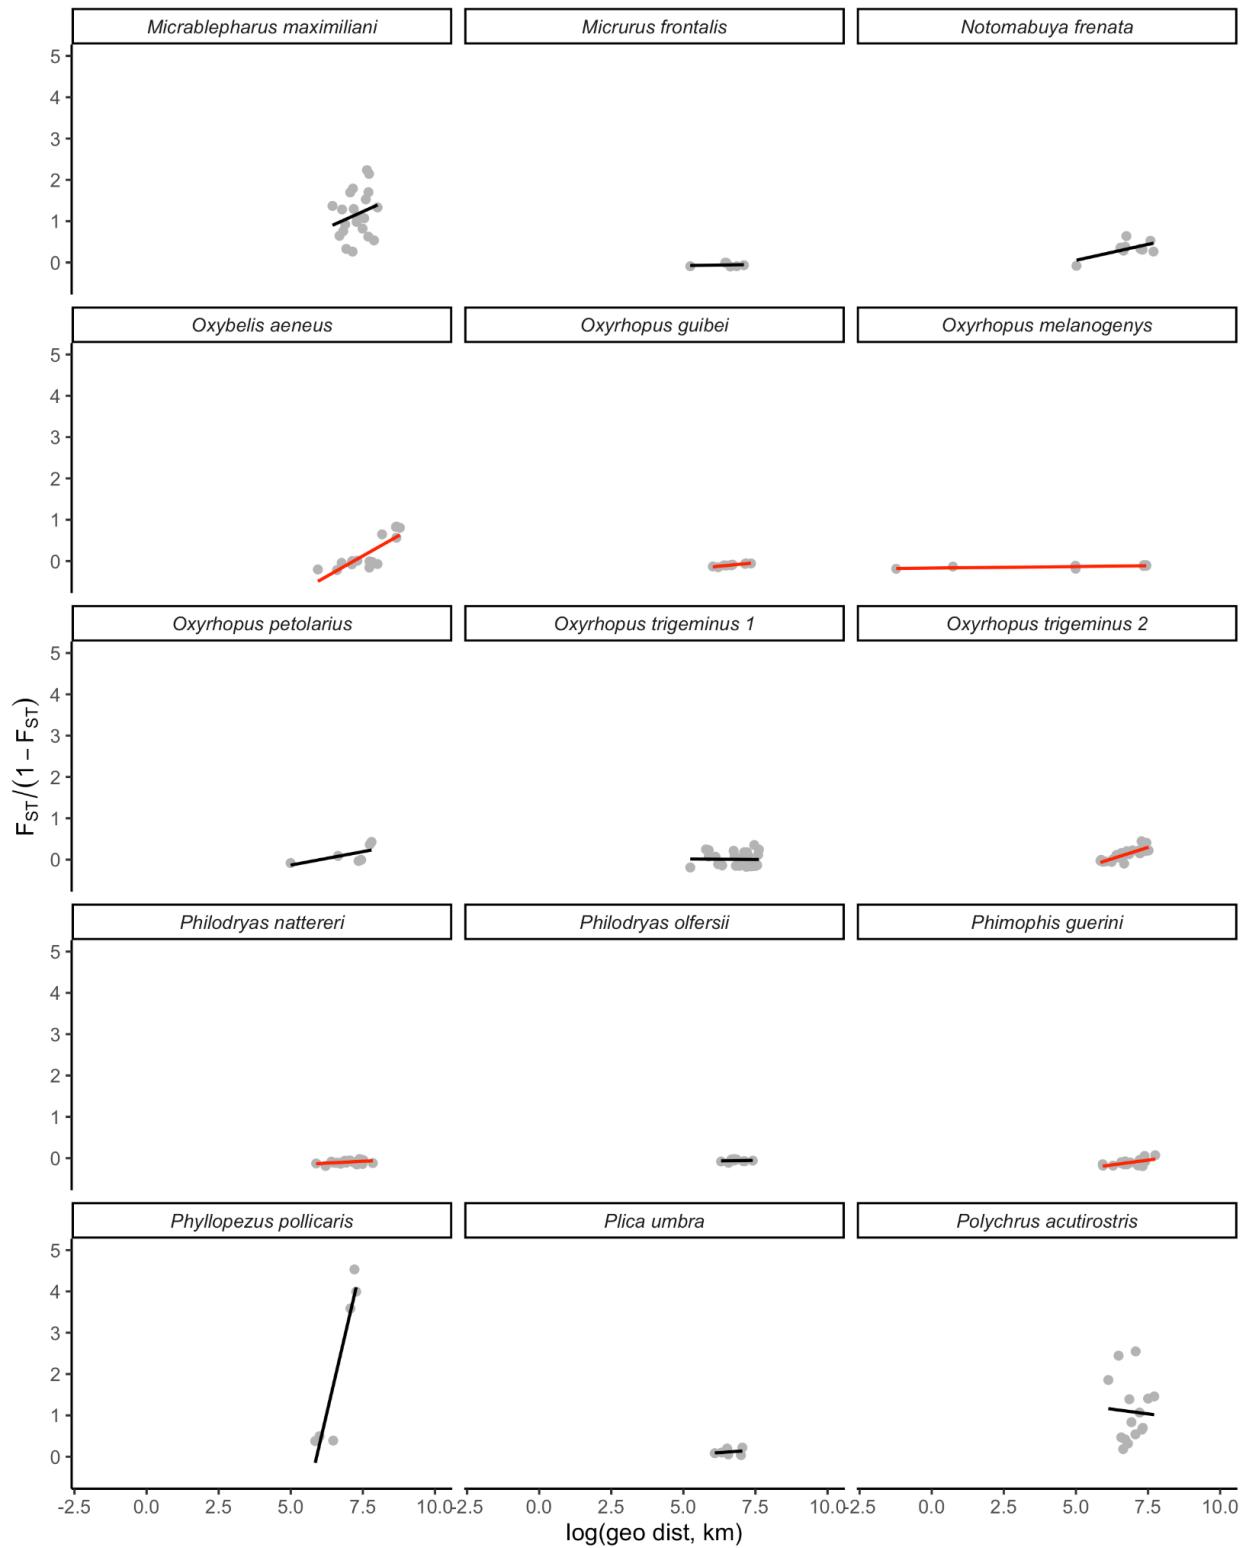

**Figure S6:** Phylogenetic data for three exemplar taxa that required subsequent refinement of operational taxonomic unit (OTU) boundaries based on phylogenetic data. (A) *Oxyrhopus trigeminus*, where samples were assigned to multiple nominate taxa that show paraphyletic relationships, (B) *Taeniophallus occipitalis*, where one individual provided evidence for a deep split within the nominal species, and (C) *Bothrops moojeni*, a species complex known to have messy taxonomic boundaries that were clarified using genetic data. The top row shows (L → R) concatenated nuclear phylogeny, concatenated mtDNA phylogeny, range maps with tips and points colored by nominal species identity, and genetic divergence across geographic space. The bottom row shows the same data for revised taxon identities. Phylogeny was dated using penalized likelihood(14) as implemented in the “chronos” function in the R package ape(15). The root age was set to 180 million years(16); scale bars reflect million years of evolution. Range maps were taken from Roll et al. 2017(13). In total, we provisionally modified 15 nominal species.

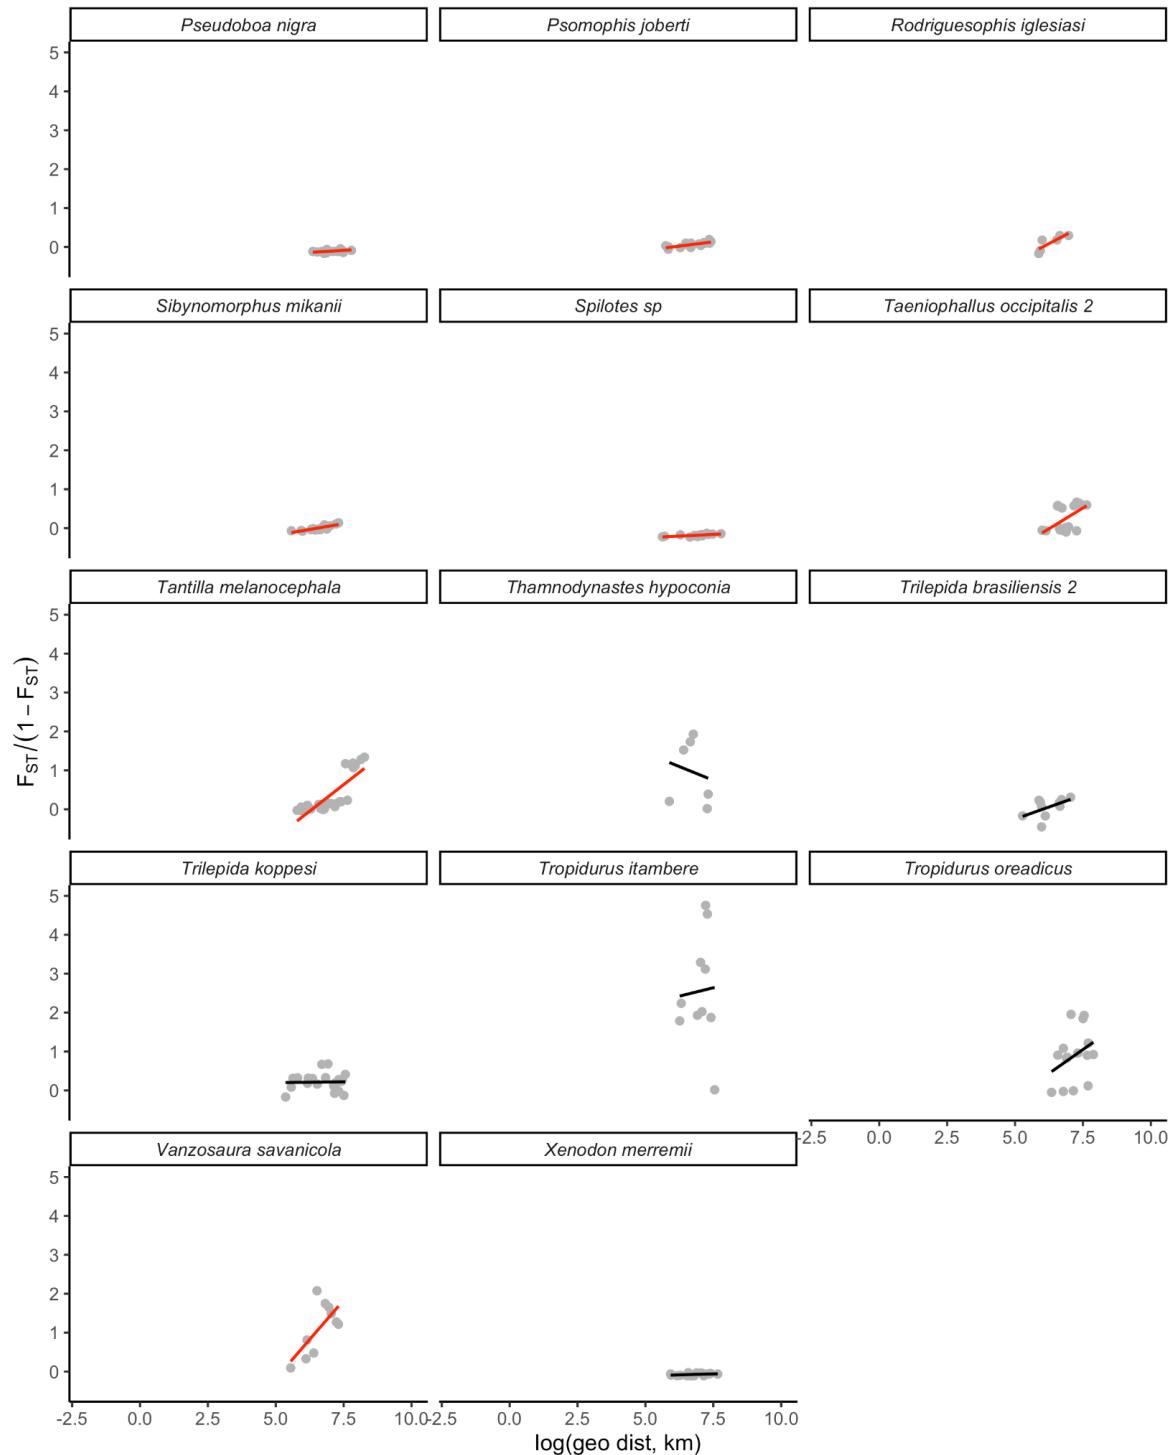

**Figure S7:** Amount of variation in genetic divergence explained by isolation-by-distance, as measured by  $r^2$  of a Mantel test comparing an inverse  $F_{ST}$  matrix to a matrix of log of geographic distance. Dark gray bars indicate significant relationships. Of the 59 species tested, 28 species returned significant isolation-by-distance models; overall, these models explained an average of 31% of the variation in genetic divergence. In our robustness analyses, we demonstrate that our overall results are unaffected by restricting our inferences to only those taxa showing strong / significant IBD relationships (Fig. S14, Table S3). In fact, the overall direction of the effect becomes negative ( $r = -0.004$ ; non-significant) when restricted to taxa with significant IBD relationships.

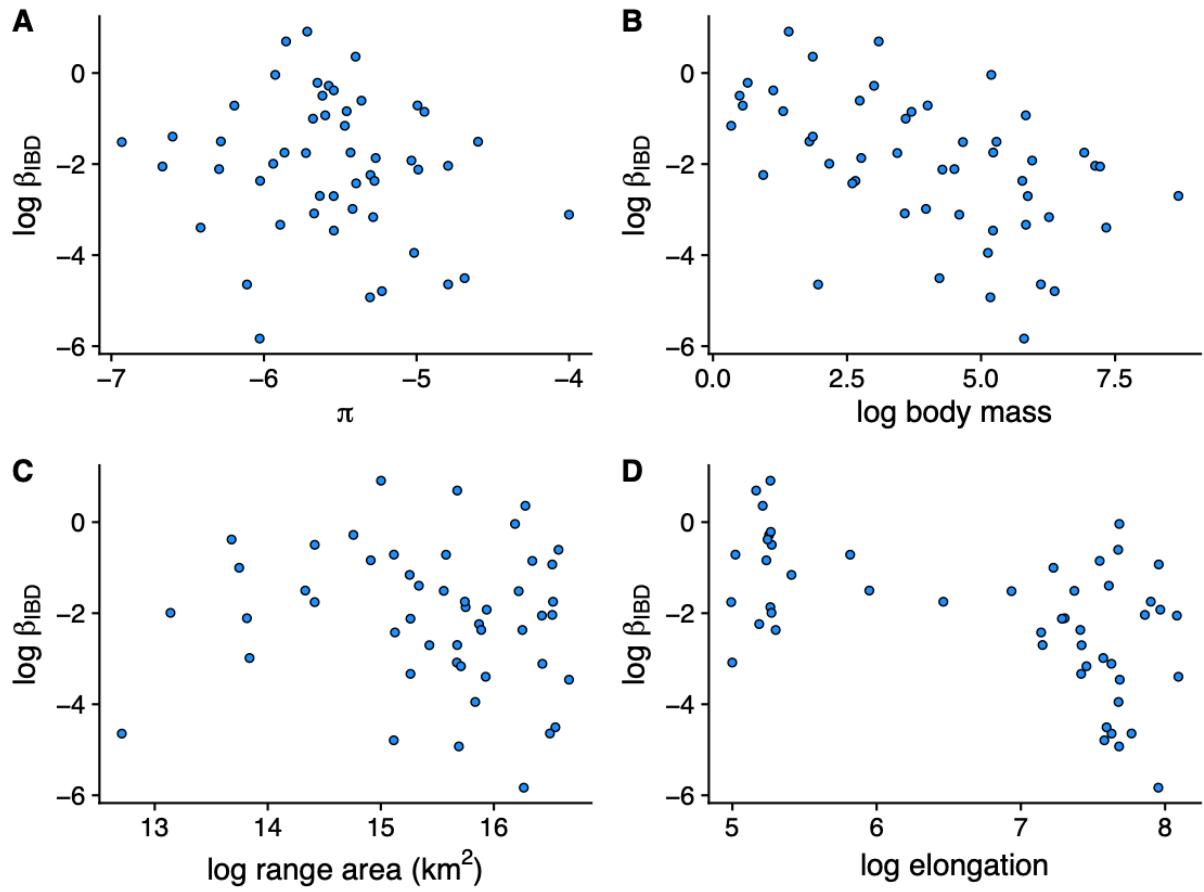

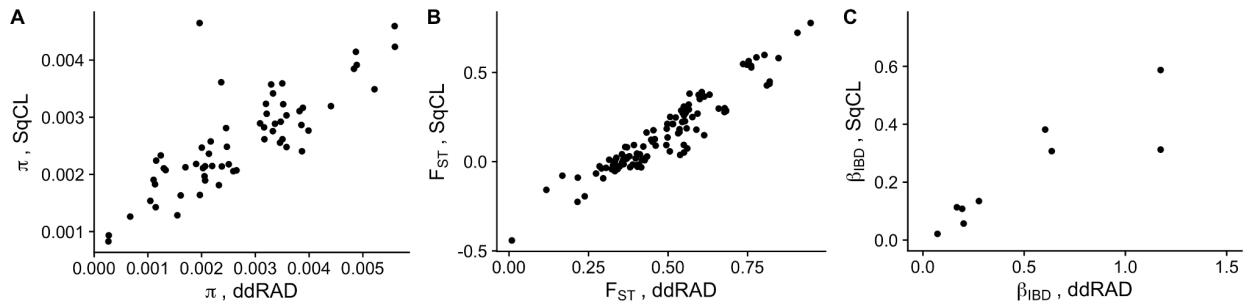

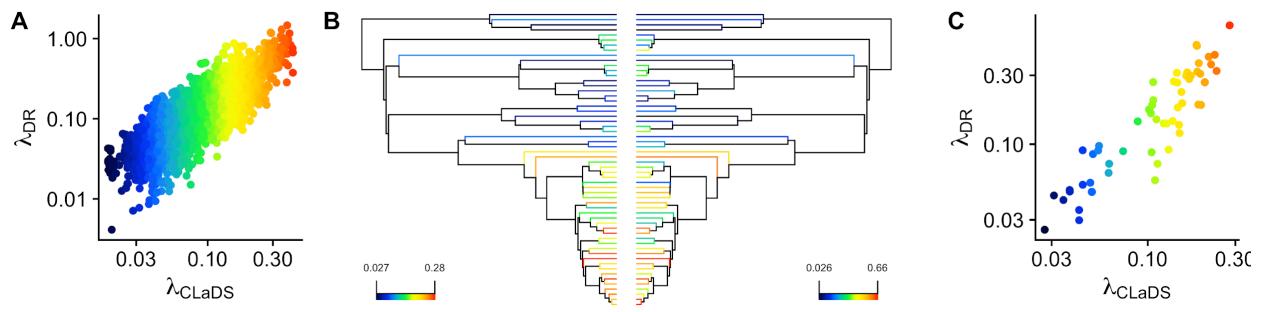

**Figure S8:** Isolation-by-distance relationships for all taxa ( $n = 59$ ) included in this study. Shown is inverse  $F_{ST}$  along the natural log of geographic distance for pairwise individual comparisons within taxa.  $\beta_{IBD}$  – our study's key metric for measuring the rate at which population isolation accumulates – is the slope of the regression line through these points. Significant  $\beta_{IBD}$  relationships are shown in red.

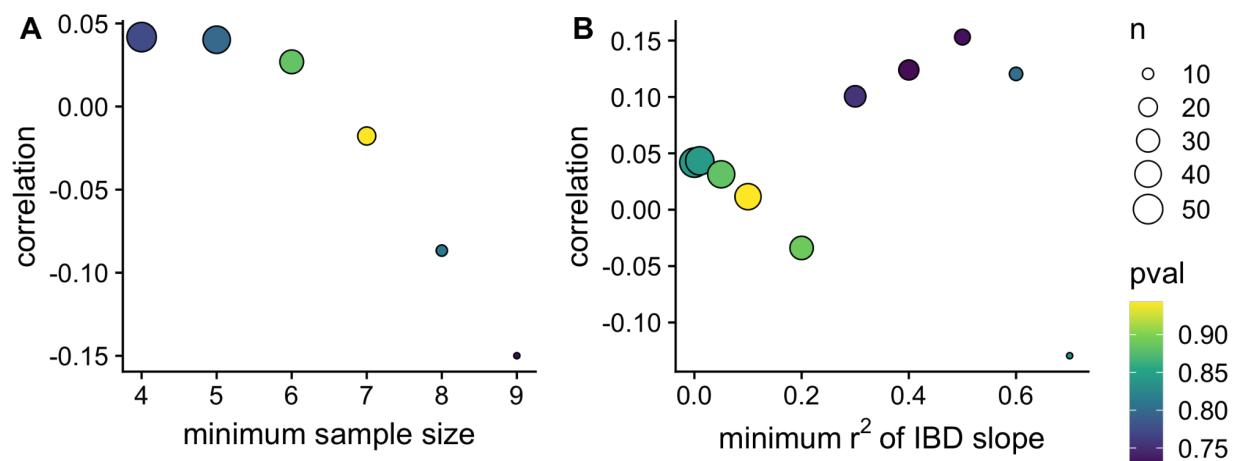

**Figure S9:** The correlation between organismal traits and slope of isolation-by-distance ( $\beta_{IBD}$ ): (A) average genetic diversity ( $\pi$ ), (B) body mass of species, (C) geographic range area, and (D) the elongation index which captures how elongated a species is. These four traits are thought to influence both population density and organismal dispersal, two factors that affect levels of isolation-by-distance. Log elongation was the only significant predictor of  $\beta_{IBD}$  (Table S2).

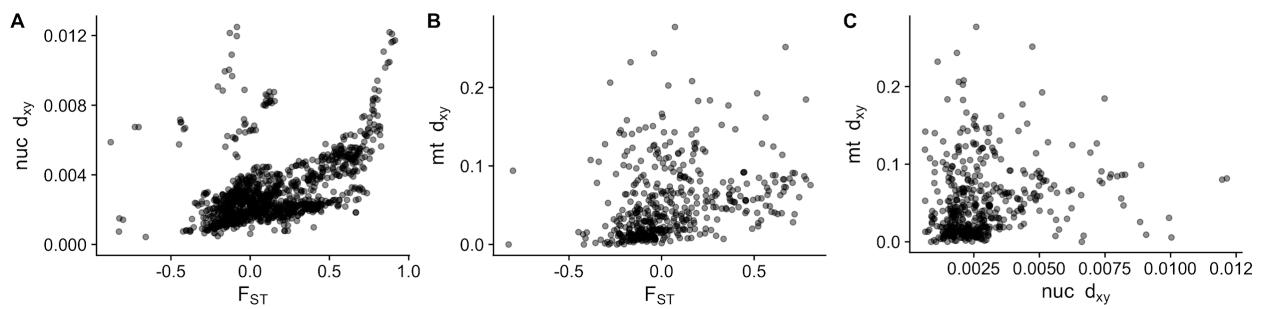

**Figure S10:** Concordance between population genetic metrics calculated using ddRAD vs. SqCL markers: (A) nucleotide diversity ( $\pi$ ), (B) genetic differentiation ( $F_{ST}$ ), and (C) slope of isolation-by-distance ( $\beta_{IBD}$ ). Estimates of genetic diversity and differentiation inferred from SqCL markers are consistently lower than those inferred from ddRAD loci, as expected given that SqCL markers are likely under stronger purifying selection than ddRAD loci. Despite this, metrics are highly correlated across both markers; Pearson correlations are (A)  $r = 0.81$ ,  $p = 3.4e-15$ ,  $n = 61$ , (B)  $r = 0.94$ ,  $p < 3e-16$ ,  $n = 110$ , and (C)  $r = 0.97$ ,  $p = 4.9e-6$ ,  $n = 10$ .

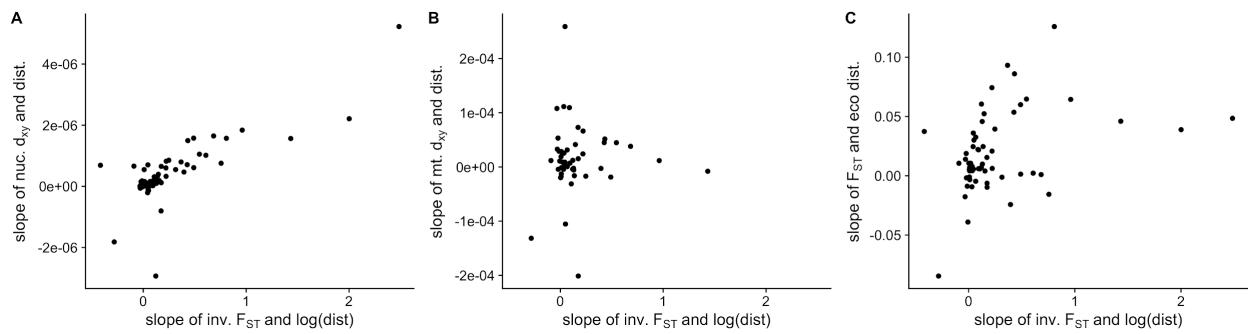

**Figure S11:** Comparison of speciation rates as estimated via a model-based approach (CLaDS,  $\lambda_{\text{CLaDS}}$ ) and a semi-parametric approach (DR statistic,  $\lambda_{\text{DR}}$ ). (A) Correlation of rates across all squamate species ( $n = 9755$ ,  $r = 0.87$ ,  $p < 2e-16$ ). (B) Comparison of speciation rates across the taxa included in this analysis; the left phylogeny shows  $\lambda_{\text{CLaDS}}$  and the right phylogeny shows  $\lambda_{\text{DR}}$ . (C) Correlation between  $\lambda_{\text{DR}}$  and  $\lambda_{\text{CLaDS}}$  across all species included in this analysis ( $n = 59$ ,  $r = 0.87$ ,  $p < 2e-16$ ). Speciation rates are highly correlated across inference methods.

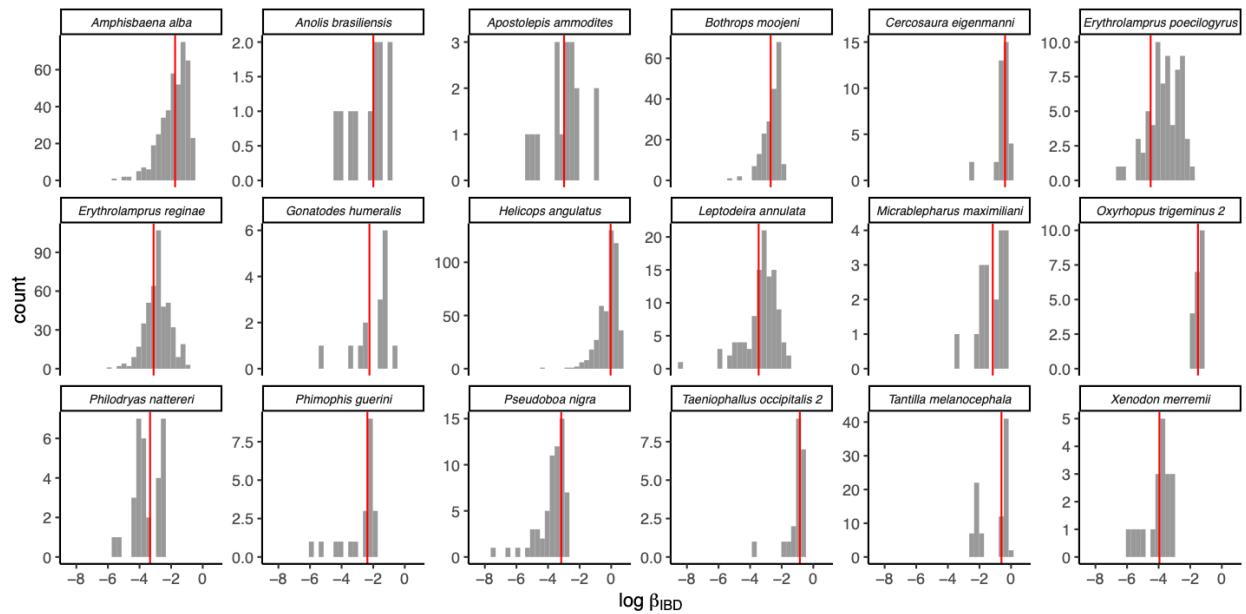

**Figure S12:** Effects of (A) sample size and (B) estimation error on correlation between isolation-by-distance (IBD) slope and speciation rate. We subsetted the dataset by filtering out taxa with (A) minimum sample sizes or (B) minimum  $r^2$  for the IBD slope estimate. For each filtered dataset, we tested the correlation between IBD slope and speciation rate. Even after removing IBD slopes with low sample size or high error, we still find no relationship between population isolation and speciation rate.

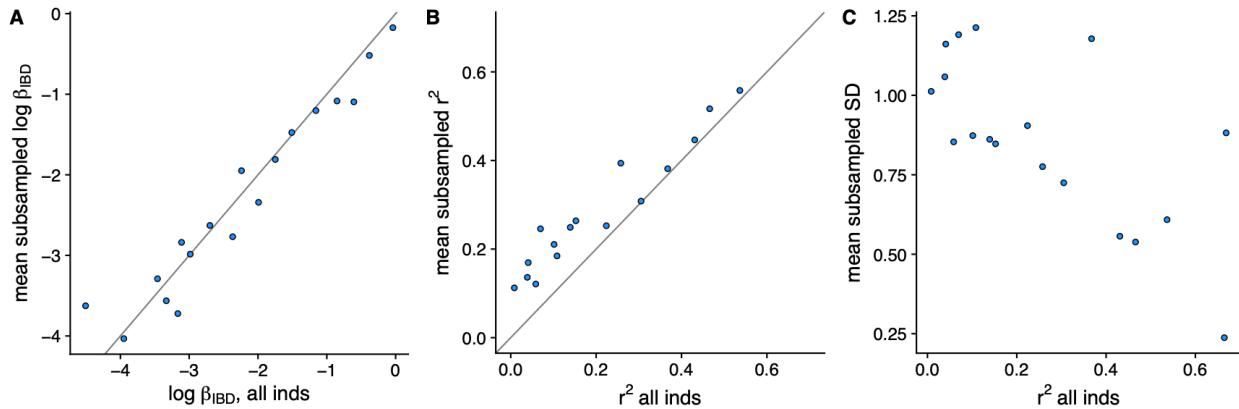

**Figure S13:** Correlation in estimates of genetic divergence across different metrics for divergence (A) nuclear  $F_{ST}$  versus nuclear  $d_{xy}$ , (B) nuclear  $F_{ST}$  versus mitochondrial  $d_{xy}$ , and (C) nuclear vs. mitochondrial  $d_{xy}$ . For (B) and (C), only pairwise comparisons where  $\geq 500$  bp of mitochondrial sequence was sampled are shown. Estimates of genetic divergence are highly correlated between nuclear estimates of divergence and more weakly between nuclear and mitochondrial divergence; Pearson correlations are (A)  $r = 0.47$ ,  $p < 3e-16$ ,  $n = 1100$ , (B)  $r = 0.30$ ,  $p = 6.9e-11$ ,  $n = 462$ , and (C)  $r = 0.16$ ,  $p = 4e-4$ ,  $n = 462$ .

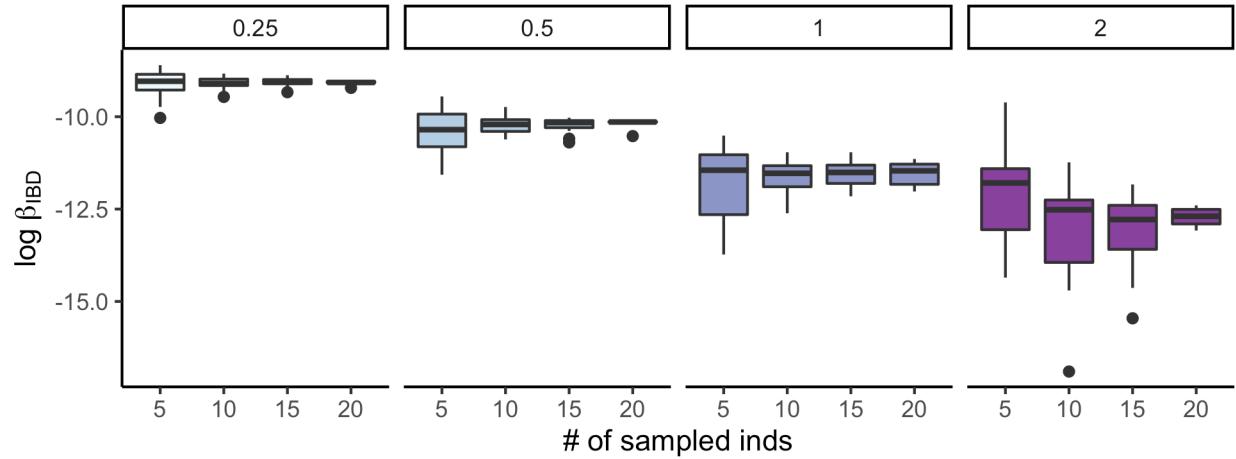

**Figure S14:** Correlations between isolation-by-distance (IBD) slopes measured using alternate metrics of genetic differentiation and distance; IBD slope between inverse  $F_{ST}$  and log geographic distance compared to (A) IBD slope between nuclear  $d_{xy}$  and geographic distance, (B) IBD slope between mitochondrial  $d_{xy}$  and geographic distance, and (C) IBD slope between  $F_{ST}$  and ecological distance. Correlations across different types of slopes vary greatly; Pearson correlations are (A)  $r = 0.79$ ,  $p = 1e-13$ ,  $n = 59$ , (B)  $r = 0.03$ ,  $p = 0.86$ ,  $n = 47$ , and (C)  $r = 0.37$ ,  $p = 0.003$ ,  $n = 59$ . However, across all alternate measures of IBD slope, we find no correlation between IBD slope and speciation rate (Table S3).

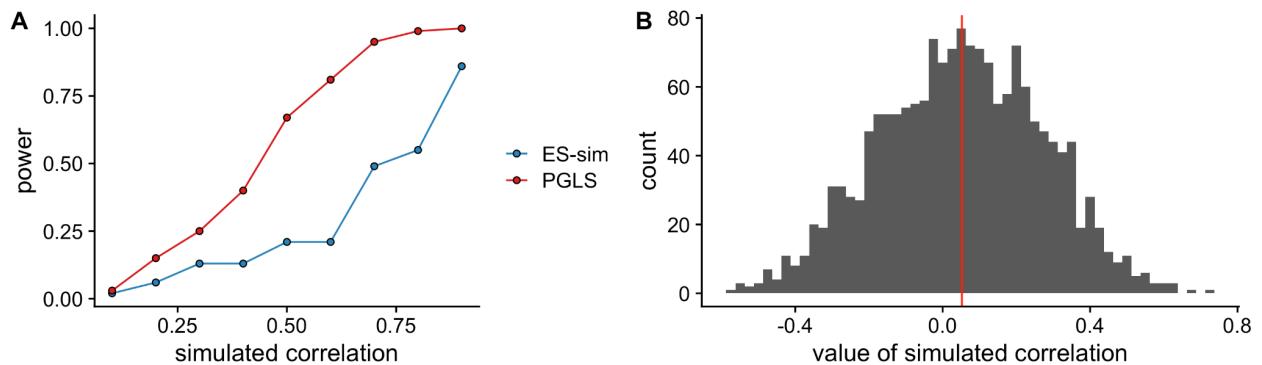

**Figure S15:** For the taxa that were sampled at  $\geq 5$  individuals, we sampled all possible combinations of 4 individuals and calculated IBD slopes ( $\beta_{IBD}$ ) for subsampled datasets. We depict here only those taxa with 10 or more subsampled datasets. Shown in gray are the subsampled slope values; shown in red is the value estimated for the complete dataset. Although some subsamples are noticeably different from those estimated with the full dataset, most subsampled datasets recover similar IBD slopes seen with the full dataset.

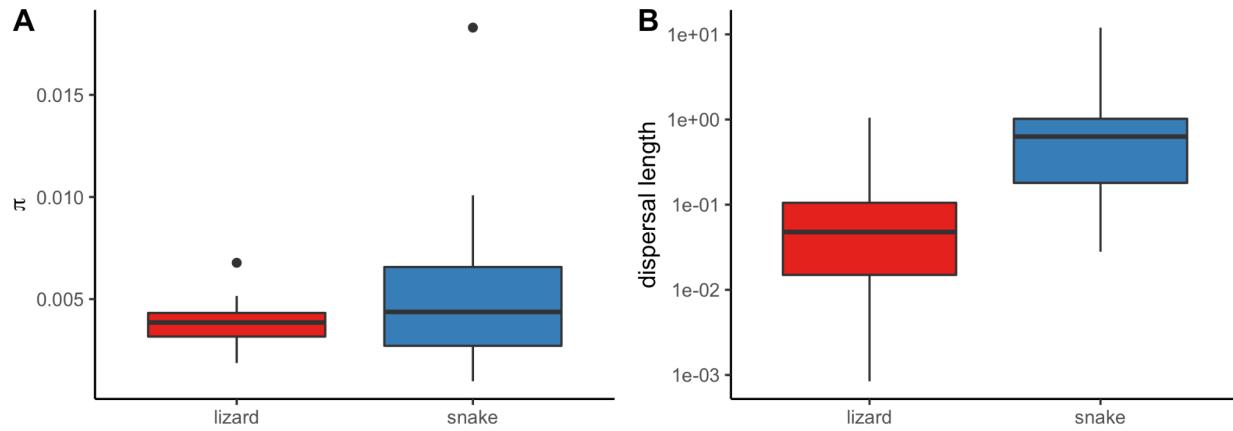

**Figure S16:** For the taxa that were sampled at >5 individuals, we sampled all possible combinations of 4 individuals and calculated IBD slopes ( $\beta_{IBD}$ ) for subsampled datasets. Shown here is (A)  $\log \beta_{IBD}$  measured across the complete sampling for a taxa versus the mean subsampled  $\log \beta_{IBD}$ , (B)  $r^2$  for  $\beta_{IBD}$  calculated across all individuals versus the mean subsampled  $r^2$ , and (C) the  $r^2$  for  $\beta_{IBD}$  calculated across all individuals versus the mean subsampled  $\beta_{IBD}$  standard deviation (SD). Gray lines in (A) and (B) are the lines of unity. Subsampled datasets have similar means and model fit as the full dataset. Further, the greater the model fit for the full dataset, the less variation we see in subsampled datasets. This suggests dropping OTUs with low model fits (see Fig. S14) is an effective way to account for limited sampling.

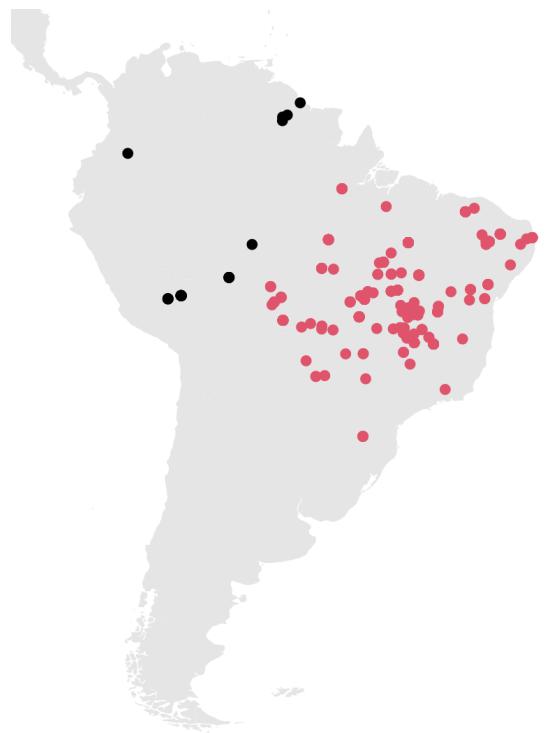

**Figure S17:** Accuracy of IBD slope estimation ( $\beta_{IBD}$ ) in forward genetic simulations. Individuals were simulated at varying levels of dispersal ( $\sigma = 0.25, 0.5, 1$ , and  $2$ ; shown by panel). We then sampled either 5, 10, 15 or 20 individuals and estimated  $\beta_{IBD}$ . Each simulation was run across 5 replicates. Even with small sample sizes, we can accurately estimate  $\beta_{IBD}$  and capture varying dispersal across populations.

**Figure S18:** Power in our study design to recover a significant correlation between log-transformed speciation rate and IBD slopes ( $\beta_{IBD}$ ) if one existed and quasi-posterior distribution of the true correlation as inferred from rejection sampling. (A) For a range of simulated correlations ( $r = 0.1$  to  $0.9$ ), for 100 simulations each, we simulated our trait of interest (here,  $\beta_{IBD}$ ) following Brownian motion under a given correlation to empirical speciation rates. We then used two methods (phylogenetic generalized least squares; PGLS) and ES-SIM to test both significance of the trait to speciation rates. PGLS had greater power to detect a correlation than ES-SIM. (B) Quasi-posterior distribution on the correlation between log-transformed speciation rate and  $\beta_{IBD}$  conditional on the phylogeny and the observed speciation rate variation, estimated using rejection sampling. Distribution was estimated using our observed correlation ( $r = 0.04$ ) as a summary statistic; correlations were sampled from a uniform (-1, 1) prior distribution and accepted if a given true correlation yielded a summary statistic that deviated by less than 0.01 from the observed value. Posterior distribution is centered approximately on zero, with a median of  $r = 0.05$  (red line). Given our estimated correlation, it is unlikely that the true correlation between population isolation and speciation rate is substantial, and it is nearly as likely to be negative as positive.

**Figure S19:** Why do more elongate animals show greater levels of isolation-by-distance? We test two possible reasons: (A) More elongate animals (e.g., snakes) have greater population density than less elongate animals (e.g., lizards), resulting in higher levels of genetic diversity ( $\pi$ ). We find no support for this hypothesis across our dataset ( $n = 59$ ; phylogenetic ANOVA  $p = 0.78$ ). (B) Snakes have greater dispersal than lizards. We summarize across 34 published studies of lizard and snake dispersal to find that snakes have  $\sim 10x$  greater dispersal than lizards (Table S4). Given that these studies use a diversity of methods and dispersal metrics, we note these results are provisional and thus do not conduct any formal statistical tests.

**Figure S20:** The effects of non-Cerrado individuals. In order to ensure our limited sampling outside of the core Cerrado region did not affect our results, we removed 36 individuals (shown in black) that fall out of the core Cerrado region and then repeated IBD slope estimation with the remaining 339 individuals (shown in pink). Using these IBD slopes, we tested our hypothesis that IBD slope predicts speciation rate, again recovering no relationship (Table S3).

## Supplemental Tables

**Table S1:** Data on the individuals ( $n = 375$ ) included in this study: nominal species designation, revised operational taxonomic unit (OTU) name provisionally used in this study, sample locality, and information on genetic data collected for sample (number of loci captured, number of sites captured in megabase (Mb), average coverage, and SRA accession ID where data can be downloaded).

| individual   | nominal species                  | revised taxon name               | latitude   | longitude  | # of loci | # of sites (Mb) | avg. cov. | SRA          |

**Table S2:** Predictors of isolation-by-distance ( $\beta_{IBD}$ ). Using phylogenetic generalized least squares (PGLS), we tested if four organismal traits predict  $\beta_{IBD}$ : average genetic diversity ( $\pi$ ), body mass of species, geographic range area, and the elongation index which captures how elongated a species is. These four traits are thought to influence both effective population size and organismal dispersal, two factors that affect levels of isolation-by-distance. Only elongation index significantly predicted  $\beta_{IBD}$ .

| Organismal Trait      | <i>n</i> | PGLS P-value |
|-----------------------|----------|--------------|
| Genetic diversity     | 50       | 0.81         |
| Body mass             | 50       | 0.82         |
| Geographic range area | 49       | 0.87         |
| Elongation index      | 50       | 0.004        |

**Table S3:** Robustness results testing the correlation between rates of population isolation and speciation rate. We tested five possible sources of error. First, we tested the role of limited sampling by removing OTUs sampled for few individuals (see full results in Fig. S14). Second, we tested the role of measurement error by (1) removing IBD slopes with low  $r^2$  values (see full results in Fig. S14), (2) removing taxa with non-significant IBD slopes ( $\beta_{IBD}$ ), and (3) using a phylogenetic mixed model in which the squared standard error of IBD slope is included as a weight. Third, we explored alternate measures of genetic differentiation across space. Fourth, we repeated analyses using nominal species designations in case our revised taxonomy is inaccurate. Fifth, we removed the few individuals sampled outside of the core Cerrado region (Fig. S20) to further control for the effects of biogeography. For each robustness analysis, we report our sample size, the estimate of phylogenetic signal for  $\beta_{IBD}$  as measured by Pagel's lambda and its p-value, and the direction of the phylogenetic generalized least squares (PGLS) correlation between  $\beta_{IBD}$  and speciation rate and its p-value.

| Type of robustness analysis           | Description   | n  | Pagel's lambda for included tips | P-val for Pagel's lambda | PGLS correlation direction | PGLS p-val |
|---------------------------------------|---|----|----------------------------------|--------------------------|----------------------------|------------|
| Primary analysis in main text         | All taxa with 4 or more sampled individuals   | 50 | 0.24                             | 0.009                    | +                          | 0.77       |

| Biogeography                          | Remove any individuals sampled outside of general Cerrado region  | 39 | 0.29                             | 0.014                    | +                          | 0.81       |

**Table S4:** Literature review on dispersal length in lizard and snake species. From 10 September to 14 September 2021, two searches were done in Google Scholar for “lizard AND dispersal” and “snake AND dispersal”. This was a non-exhaustive search, and the first ~50 citations under each search were reviewed to extract information on dispersal length, units, and approach used to measure dispersal.

| species                             | dispersal | dispersal units | citation                    | dispersal type  | Taxa type |
|-------------------------------------|-----------|-----------------|-----------------------------|---|-----------|
